### 15 **Abstract**

16 The objective of the Nordic Snow Radar Experiment (NoSREx) campaign was to provide a  
17 continuous time series of active and passive microwave observations of snow cover in a  
18 representative location of the Arctic boreal forest area, covering a whole winter season. The  
19 activity was a part of Phase A studies for the ESA Earth Explorer 7 candidate mission  
20 CoReH2O (Cold Regions Hydrology High-resolution Observatory).

21 The NoSREx campaign hosted two main microwave instruments; a frequency scanning  
22 scatterometer operating on frequencies from X- to Ku band, and a microwave dual-polarization  
23 radiometer system operating from X- to W bands. In situ measurements consisted of manual  
24 snow pit measurements at the main test site as well as extensive automated measurements on  
25 snow, ground and meteorological parameters.

1 This study provides a summary of the obtained data, detailing measurement protocols for  
2 both microwave instruments and in situ reference data. A first analysis of the microwave  
3 signatures against snow parameters is given.

4 All data, including the raw data observations, are available through the European Space Agency  
5 and the Finnish Meteorological Institute for research purposes. A consolidated dataset of  
6 observations, comprising of the key microwave and in situ observations, is provided through  
7 the ESA campaign data portal to enable easy access to the data.

8

## 9 **1 Introduction**

10 Knowledge on the duration, extent and total mass of seasonal snow cover is crucial for  
11 hydrological forecasts, numerical weather prediction and estimation of the energy balance of  
12 the Earth (Groisman et al., 1994; Brasnett, 1999; Barnett et al., 2005). Seasonal snow cover is  
13 also a strong indicator of global climate change (Derksen and Brown, 2012). The scarcity of  
14 observation networks makes data collected *in situ* unreliable for Arctic and boreal areas, making  
15 Earth Observation from satellites an appealing option. The extent of seasonal snow cover can  
16 be retrieved with high spatial accuracy using both optical and radar sensors. Methods for  
17 retrieving snow mass, or snow water equivalent (SWE), presently rely on passive microwave  
18 sensors (Kelly et al., 2003; Takala et al., 2011). Although these provide good global coverage  
19 and a long history of observations, present products suffer in accuracy from the inherent coarse  
20 spatial resolution of passive microwave sensors over inhomogeneous areas.

21 Providing high-resolution information on the mass of seasonal snow cover was the main  
22 objective of CoReH2O (Cold Regions Hydrology High-Resolution Observatory), a candidate  
23 mission for the European Space Agency's 7th Earth Explorer (ESA, 2012). The payload of  
24 CoReH2O was envisaged as a dual-polarized, dual-frequency (X and Ku band) synthetic  
25 aperture radar (SAR), with the capability of detecting SWE, as well as snow accumulation on  
26 glaciers, at spatial resolutions ranging from 200 to 500 m (Rott et al., 2012). In order to support  
27 the development of geophysical retrieval algorithms for CoReH2O, the NoSREx (Nordic Snow  
28 Radar Experiment) was initiated by ESA in 2009. The aim of the campaign was to collect near-  
29 continuous observations of snow cover radar signatures in the boreal forest/taiga region using  
30 a tower-based configuration, supported by frequent in situ observations. The campaign was  
31 designed to cover entire winter periods from snow free conditions to eventual snow melt-off.  
32 With several extensions, the collected dataset for NoSREx covers a total of four snow seasons

1 from 2009 to 2013. The campaign was conducted at the Finnish Meteorological Institute Arctic  
2 Research Centre (FMI-ARC) in Sodankylä, Finland. The radar backscatter measurements were  
3 complemented by multi-frequency microwave radiometer observations and numerous in situ  
4 observations of snow, soil and atmospheric properties, using both manual and automated  
5 methods. Advanced methods for quantifying the snow microstructure were implemented on a  
6 campaign basis. The campaign provides a unique, near-continuous dataset of coinciding active  
7 and passive microwave observations of snow cover and diverse measurements of snow  
8 characteristics. During the last two seasons, airborne acquisitions using the ESA SnowSAR  
9 instrument were made over the area in order to analyse spatial variability of backscattering and  
10 to demonstrate the CoReH2O mission concept (see e.g. ESA 2012; Lemmetyinen et al., 2014).  
11 However, these data are not presented here.

12 Data collected during NoSREx have found use in numerous recent studies exploring the  
13 modelling of microwave signatures of snow covered terrain. Here, we provide an overview of  
14 the used instrumentation, data acquisition protocols and the collected microwave signatures.  
15 The calibration accuracy of the various instrumentation is discussed. We also give  
16 recommendations and suggestions on how in situ data could be used optimally to support  
17 analysis of microwave observations. We discuss recent studies which have already exploited  
18 the results of the campaign, and give recommendations for future experimental campaigns on  
19 snow microwave signatures.

20

## 21 **2 Description of experiment setup**

### 22 **2.1 Measurement location**

23 The main test site of NoSREx, the Intensive Observation Area (IOA), was located on a forest  
24 clearing surrounded by a sparse spruce/pine dominated forest. The site, as well as the area at  
25 large, represents a typical boreal forest/taiga landscape. According to a soil composition survey,  
26 soil at the IOA consisted of sand (70%), silt (29%) and clay (1%) with a thin organic surface-  
27 layer (2 - 5 cm). The sparse ground vegetation consisted mainly of lichen and heather and other  
28 small vegetation typical for the boreal forest region. Small trees and bushes estimated to  
29 influence e.g. snow accumulation were manually removed from the site in autumn before the  
30 onset of snow cover.

1 The main microwave instruments installed were the *SnowScat* scatterometer (Werner et al.,  
2 2010) and the *SodRad* multi-frequency radiometer system. Data from an L-band instrument  
3 (Schwank et al., 2010) is available from the same site, but these data are not discussed here. All  
4 instruments were mounted on tower structures overlooking the forest clearing, allowing  
5 partially to cover also same sectors of the test field, albeit at differing effective incidence angles.  
6 Automated sensors were located adjacent to the test field, as was the main location for manual  
7 snow measurements. The location of the microwave instrumentation, as well as the approximate  
8 locations of various in situ sensors are depicted in Figure 1. The measurement protocols for  
9 each instrument are described in detail in the following sections.

10

## 11 2.2 Microwave scatterometry

12 The *SnowScat* scatterometer, manufactured by Gamma Remote Sensing, is a frequency step  
13 four-polarization scatterometer (VV, HH, VH and HV), operating between the frequency range  
14 of 9.2 and 17.9 GHz (Werner et al., 2010). Equipped with a positioner device, the system allows  
15 scanning in both azimuth and elevation. For NoSREx, the instrument was installed on a tower  
16 structure at the height of 9.6 meters above ground overlooking the IOA. The instrument was set  
17 to measure regular scans of the test field, first every three hours in 2009. The scan of the main  
18 measurement sector (sector 1) comprised of 17 independent look directions in azimuth at four  
19 incidence angles at 30, 40, 50 and 60 degrees. From the autumn of 2010, the scan interval was  
20 increased to four hours to allow for scanning over an additional sector (sector 2) adjacent to the  
21 main observation section (see Figure 1). The data presented in this study consists of calibrated  
22 sigma nought values, averaged over the full azimuth scan of sector 1. Sector 2 data, however,  
23 are included in the NoSREx consolidated datasets. The technical specifications of *SnowScat* are  
24 given in Table 1.

25 *SnowScat* provided an internal calibration loop for compensation of internal temperature  
26 changes. The calibration consistency was verified by measuring dedicated calibration targets  
27 before and after each scan (a ~20 cm diameter sphere for all seasons, and for the third and fourth  
28 seasons, an additional flat plate target enabling assessment of cross-pol accuracy). A typical  
29 variability of co-polarized backscatter from the calibration sphere was measured to be less than  
30 +/- 1dB.

1 The measurement protocol of *SnowScat* included two measurements of the calibration sphere  
2 for reference purposes. In addition, the metal plate was measured for reference purposes during  
3 NoSREx III and IV. The nominal scan sequence was

- 4 • Cal sphere measurement
- 5 • Plate measurement (for NosREx III and IV)
- 6 • Sector 1 scan
- 7 • Cal sphere measurement
- 8 • Plate measurement (for NosREx III and IV)
- 9 • Sector 2 scan (for NosREx II to IV)

10

### 11 **2.3 Microwave radiometry**

12 The *SodRad* system, including measurements at 10.65, 18.7, 21, 37 and 90 GHz (H and V  
13 pol), was mounted on a 4.1 m-high platform overlooking the forest clearing. The 90 GHz  
14 radiometer was available from 2009 until 2012, when it was replaced by the 21 GHz system.  
15 Measurements were made by performing a scan in the elevation direction, resulting in ground  
16 incidence angles from 30 to 70° off nadir, in steps of 5°. Although the system allowed scans in  
17 azimuth, most measurements were made in a single azimuth direction. In order to avoid RFI  
18 contamination in particular at the 10.65 and 18.7 GHz systems, the measurements were timed  
19 to occur between scans of the *SnowScat* instrument. Thus, the elevation scan was performed  
20 every three hours during 2009-2010, and every four hours in following winters. In between  
21 elevation scans, *SodRad* was set to measure a fixed incidence angle (50 or 53 degrees,  
22 depending on season). These data are available upon a separate request. The technical  
23 specifications of *SodRad* are given in Table 2.

24 The measurement sequence of *SodRad* consisted of

- 25 • the elevation scan
- 26 • a measurement of the sky cold target reference at zenith (10 minutes)
- 27 • a fixed angle measurement (until next elevation scan)

28 The tower-based radiometers were calibrated using a two-point calibration with external  
29 targets, using a microwave absorber at ambient temperature and a similar target cooled by liquid  
30 nitrogen. Verification of calibration stability was performed using the cold sky reference at  
31 zenith (imposing a minimal influence from changing atmospheric conditions) after each

1 elevation scan. Additional calibration experiments included measurements of external targets  
2 before and after the campaign season, including absorber material cooled by liquid nitrogen.  
3 Analysis of the cold sky measurements indicates a drift of less than  $< 2$  K for all channels and  
4 polarizations (using only measurements made under clear sky conditions). Absolute accuracy  
5 of the calibration was estimated to be better than 1 K for the 18.7 and 36.5 GHz channels, and  
6 better than 2 K for the 10.65 GHz channels. The increased uncertainty of the 10.65 GHz  
7 channels is due to use of a large parabolic reflector in front of the antenna feed, whereas 18.7  
8 and 36.5 GHz channels utilize horn antennas; the parabolic reflector exhibited some sidelobe  
9 effects which could not be entirely removed in the calibration.

#### 10 **2.4 Manual in situ data collection**

11 Manual snow observations consisted of weekly snowpit measurements. Snowpits were made  
12 at a distance of ca. 10-20 meters from the radiometer footprints in the same measurement field  
13 (Figure 1). Due to the destructive nature of snowpit measurements, consecutive pits were made  
14 at a distance of 50-100 cm from the previous pit. Measured parameters included bulk snow  
15 depth, density and SWE using a snow corer and manual scale, snow density profiles at 5 cm  
16 intervals using a 250 cm<sup>3</sup> manual cutter and scale, snow temperature profile at 10 cm intervals  
17 using a digital thermometer, an assessment of snow layering based on a manual assessment of  
18 snow hardness variations, and snow grain size and type estimation. The snow grain size and  
19 type were estimated visually from macro-photography of snow samples, taken against a 1-mm  
20 reference grid. A grain size classification was made following Fierz *et al.* (2009); in addition,  
21 the typical grain size (average maximum diameter of typical snow grains, referred to hereafter  
22 as  $E$ ) was estimated visually. One snow sample was taken from the centre of each identified  
23 snow layer, and the estimated grain size of the sample was considered to be applicable for the  
24 whole layer.

25 During the third and fourth campaign seasons, snow Specific Surface Area (SSA) was  
26 measured with the IceCube instrument manufactured by A2 Photonic sensors, France. The  
27 measurement is based on IR reflectance of a snow sample placed inside an integrating sphere  
28 (Gallet *et al.*, 2009). The vertical snow profile was sampled at 3 cm resolution, excluding hard-  
29 packed layers which presented difficulties for sampling. The time series of SSA measurements  
30 are not a part of the NoSREx consolidated datasets but are available on separate request.

31 As snow pit observations were not made directly in the footprint of microwave instruments,  
32 with the exception of specific tests (see Proksch *et al.*, 2015), the snow profile information

1 should be treated with caution. In addition to temporal variability, also the spatial variability of  
2 snow should be considered. As this can be notable even at short distances, it is not  
3 recommended to use the measured profiles as they are for direct estimation of snow properties  
4 at the instrument footprints. Rather, e.g. Lemmetyinen et al. (2015) applied a simplification of  
5 the measured snow profiles to either one or two layers. In addition, a third order fit was applied  
6 to the observations of  $E$  to reduce uncertainty arising e.g. from observer bias.

7

## 8 **2.5 Automated in situ data**

9 Several automatic measurement instruments were installed at the IOA. Two acoustic sensors  
10 were used to record snow depth ( $SD$ ). One sensor was placed in the forest clearing near the  
11 *SodRad* platform tower and another under the forest canopy at a distance of ca. 50 meters. Air  
12 temperature ( $T_{\text{air}}$ ) was measured at the same locations. Three automated soil moisture and soil  
13 temperature measurement sensors were installed at different locations in the test field. Snow  
14 Water Equivalent was measured directly with an experimental device (GWI, Gamma Water  
15 Instrument). Data from other automated in situ observations were collected into the  
16 consolidated datasets from the FMI sounding station (ca. 500 meters from the IOA) and  
17 Meteorological mast, in the immediate vicinity of the IOA.

## 18 **2.6 Intensive observation periods**

19 Intensive Observation Periods (IOPs) were organized during the first three NoSREx  
20 campaigns. The objective of the IOPs was to complement the collected time series of basic  
21 observations, in particular by employing advanced methods for characterization of snow  
22 microstructure. The measurements consisted of

- 23 • SSA analyses using Near-Infrared (NIR) photography (Matzl et al., 2006)
- 24 • Snow micropenetrometry using the Snow MicroPen, (SMP, Schneebeli et al., 1998;  
25 Proksch et al., 2015)
- 26 • Computer Tomography (CT) analysis of casted snow samples (Matzl et al., 2010)

27 .In particular, the measurements provide a means to validate visual estimations of layering  
28 against SMP profiles, validate and compare visual grain size estimates against correlation  
29 length from CT imagery, validate density profile measurements against density profile from CT

1 analysis, and estimate the 3D distribution on main sites now stratigraphy from SMP  
2 measurements surrounding test field.

3 The data can be used to drive forward models for emission and backscatter directly for the  
4 date when measurements are available, providing a possibility to accurately study the effect of  
5 small scale snow characteristics on emission and backscatter. As in the case of conventional  
6 snow pit observations, most measurements were made outside of the instrument footprints.  
7 However, as a one-time test during the third campaign period, SMP measurements and casted  
8 CT samples were taken from an area in the test field observed by both *SnowScat* and *SodRad*  
9 (Proksch et al., 2015). Data from IOPs are not a part of the NoSREx consolidated datasets but  
10 can be made available on request from FMI.

11

### 12 **3 NoSREx consolidated datasets**

13 The key observations of NoSREx are collected in a consolidated dataset, providing easy access to  
14 the main time series of *in situ* and microwave measurements. The data are provided as csv (comma  
15 separated value) files and Excel spreadsheets. The data include

- 16 • Calibrated time series of *SnowScat* backscatter sigma nought at four incidence angles (30, 40,  
17 50 60°) and three 2 GHz frequency bands (centre frequencies 10.2, 13.3 and 16.7 GHz). Separate  
18 data files are provided for the two measurement sectors (sector 1 = main measurement sector;  
19 sector 2 = adjacent sector). Data are provided as averages over the full azimuth scan range of  
20 both sectors, with the exception that some azimuth directions have been removed from the sector  
21 1 data to avoid experimental plate targets set in 2010. NOTE: *SnowScat* consolidated data for  
22 the third campaign season (2011-2012) is limited to a period after January 20<sup>th</sup>, 2012, due to  
23 observed anomalies in the backscatter data.
- 24 • Calibrated time series of *SodRad* brightness temperatures at 10.65, 18.7, 37 and 90 GHz, H and  
25 V pol, at four incidence angles (30, 40, 50 60°). Average value and standard deviation of each  
26 elevation scan provided. The 90 GHz receiver was replaced by a 21 GHz receiver from autumn  
27 2011 onwards.
- 28 • Time series of selected automated *in situ* observations at the IOA, the main FMI-ARC  
29 automated weather station (AWS), the Meteorological mast. Data provided as average values  
30 over the scan times (three or four hours) of *SnowScat* observations. Recently, an updated version  
31 with one hour averages has been made available.
- 32 • Summary of weekly and bi-weekly manual snow pit measurements at the IOA.

33

## 1 **4 Overview of collected data from NosREx I to IV**

2 The NoSREx campaign seasons each had each distinctive characteristics concerning weather  
3 conditions, snow structure, and soil conditions. All of these affected the resulting microwave signatures,  
4 which are discussed in this section.

### 5 **4.1 Weather and snow conditions**

6 The four winter seasons covered by NosREx are summarized in the following in terms of weather,  
7 snow and soil conditions. The distinctive characteristics of each season of NoSREx are collected in  
8 Table 3, showing also a comparison to the 30-year average in the Sodankylä region.

9 For the first season (NoSREx I), the early onset of permanent snow cover (Day of Year [DOY] 279)  
10 and mild temperatures were clearly linked to a delayed evolution of soil freezing. Melt-refreeze events  
11 in December also caused the formation of a crust at the bottom of the snowpack. The maximum  
12 measured SWE was slightly over the 30 year average, while based on snow pit observations, depth hoar  
13 was largely absent. The following season (NoSREx II) saw a sharp onset of soil freezing; at its  
14 maximum, the measured soil frost depth was over 2 meters on March-April 2011. The season saw harsh  
15 temperatures in early winter and a relatively thin snow cover, with a maximum SWE of only 165 mm,  
16 the lowest maximum value for the three years investigated. This caused rapid freezing of the soils as  
17 well as the formation of a distinct depth hoar layer in the snow, which is exhibited by the highest average  
18 estimated snow grain size. The average bulk snow density was also notably low ( $0.17 \text{ g/cm}^3$ ).

19 Despite late onset of permanent snow cover (DOY 329), the third season of observations (NoSREx  
20 III) saw the thickest snow cover of the campaign, with a maximum recorded SWE value of 240 mm,  
21 and the lowest penetration of soil freezing, the largest measured value being 120 cm. The early season  
22 was exceptionally mild in temperatures. The thermal winter begun later than during the previous two  
23 years, with a relatively thick snow pack already present. As a result, the development of soil frost was  
24 initially slow, and soil temperature remained at  $\sim 0^\circ\text{C}$  well past the beginning of February (see Figure  
25 2c), indicating residual free water in the top soil. Snow pit information indicated that the formation of  
26 depth hoar was very weak in the early the season, due to the small temperature gradient between the top  
27 and bottom of the snowpack. Despite the subjective nature of visual grain size estimates, it can be  
28 concluded that the average grain size of the snow was clearly smaller during NoSREx III than the  
29 preceding two seasons, largely due to the absence of large depth hoar crystals in the dataset.

30 The fourth season exhibited soil and snow conditions close to the 30-year average. Compared to  
31 preceding seasons, the estimates of snow grain size were on average the smallest after the third season  
32 ( $E = 1.1 \pm 0.3 \text{ mm}$ ), while the SWE maximum fell between the first and second seasons.

33  
34

## 1 4.2 Microwave signatures against snow and soil conditions

2 Figure 2 presents the time series of observations for the four seasons of NoSREx,  
3 summarizing some of the microwave and *in situ* information available. Co-polarized (VV-  
4 polarization) backscatter measurements from the *SnowScat* instrument measured at 50 degree  
5 incidence angle are given for the three 2 GHz frequency bands available in the consolidated  
6 datasets (centre frequencies at 10.2, 13.3 and 16.7 GHz). Vertically polarized *SodRad*  
7 observations at 18.7 and 37 GHz, typically used for detection of snow water equivalent, are  
8 displayed for the same time periods. Selected *in situ* observations include snow depth ( $SD$ ), air  
9 temperature ( $T_{air}$ ), ground temperature ( $T_G$ ), bulk averages of manually measured snow density  
10 ( $\rho_s$ ) and bulk averages of visual estimates of snow grain size ( $E$ ). The microwave instruments  
11 suffered from installation delays and malfunctions, which appear as data gaps in the autumn  
12 seasons of 2009, 2011 and 2012. Specialized tests and maintenance periods took place also in  
13 April 2010, April 2012 and February/March 2013. Notably, continuous measurements from  
14 snow free conditions to snow melt-off are available only for the second campaign season.

15 The microwave signatures reveal some interesting characteristics; in particular, the early  
16 snow season response was characterized by sudden decreases in backscatter, originating from  
17 snow melt events, followed by an increase in backscatter during refreezing. Several such  
18 periods occurred e.g. in the autumns of 2009 and 2010; for 2010, the same features can be  
19 observed in *SodRad* brightness temperatures. A distinct feature observed during the first,  
20 second and fourth seasons, was a gradual decrease of backscatter after the initial increase  
21 (measurements during the early winter of the third season, until January 2012, were lost due to  
22 an erroneous setting in the *SnowScat* instrument). The effect can be explained by the gradual  
23 relaxation of crust structures in snow, formed during the early season melt events, to more  
24 typical late-winter snow. The fact that the effect is more discernible at 16.7 GHz than at the two  
25 lower frequency bands implies that the feature is dominated by changes scatter in the snow  
26 volume. Unfortunately, the *in situ* data was not able to provide a quantitative measure of the  
27 phenomena, as objective measurements of the snow structure (e.g. computer tomography  
28 samples, see section 2.6) were not taken in the early season. Nevertheless, the observations are  
29 consistent with the expected backscatter behaviour of snow undergoing metamorphism.

30 Overall, there is very low response at X-band (10.2 GHz) to changing snow conditions  
31 during the entire snow season, with signatures during the first and third seasons showing even  
32 a continuous decreasing trend in backscattering intensity. The response at the low Ku band

1 (13.3 GHz) shows some increase in intensity during the first and second seasons (Figure 2a and  
2 b), while during the third season (Figure 2c) no increase is apparent. A notable response at the  
3 higher Ku-band (16.7 GHz) is observed for the first, second and fourth seasons. However, in  
4 particular during the last season (Figure 2d), the increase in backscattering cannot be attributed  
5 to increase in snow mass, as the measured snow height and density remained almost constant  
6 from March to April 2013, when an increase of Ku band backscattering was observed. Rather,  
7 the increase can be related to the observed increase in snow grain size.

8 The measured *SodRad* brightness temperature response showed clear similarities with the  
9 backscatter measured by *SnowScat*. In particular, the dynamic responses of both the 18.7 and  
10 37 GHz channels were strongest for the second season ((Figure 2b), and notable also for the  
11 first season ((Figure 2a; note: early season dynamics not visible due to late start of  
12 measurements). Signal dynamics at 37 GHz were much reduced during the third campaign  
13 season (Figure 2c), indicating a low amount of total scattering in the snowpack, despite the third  
14 year exhibiting the highest total SWE.

15 It should be noted that for the first and third campaign seasons, measurements were begun  
16 only after the onset of snow cover. Furthermore, in November 2012, *SodRad* measurements  
17 were halted due to maintenance immediately after onset of snow cover. The early season drop  
18 of the 37 GHz brightness temperature is thus not apparent in the data for those seasons. The  
19 *SodRad* instrument also malfunctioned in early April 2012, missing the last significant increase  
20 in SWE of the season.

21 The small average  $E$  during NoSREx III (1.0 mm, compared to 1.4 and 1.5 mm for NoSREx  
22 I and II, respectively) may explain in part the diminished dynamics of the backscatter and  
23 emission signals observed during this season. The low bulk average value of  $E$  reflects mainly  
24 the lack of a depth hoar layer during NoSREx III, whereas for NoSREx II a significant layer of  
25 depth hoar was observed. For the first NoSREx season, large grains were prominent in the lower  
26 snow layers due to early formation of melt-refreeze crusts.

27 A declining trend towards the late season can be observed in the 3<sup>rd</sup> order fit of  $E$  in particular  
28 for the first and second campaign seasons (Figure 2a and b); this can be explained by newly  
29 fallen layers of snow with a small grain size forming an increasingly large part of the total  
30 snowpack, thus affecting the bulk average. For the fourth campaign season (Figure 2d), the  
31 average grain size was observed to increase almost monotonously for the entire dry snow  
32 season. This may explain why both the 16.7 GHz backscattering and 37 GHz emission

1 signatures continue to indicate increasing scattering in the snow, despite the snow height  
2 remaining almost constant between March and April 2013.

### 3 **5 Model analysis**

4 To demonstrate the use of the NoSREx data in evaluation of microwave emission and  
5 backscattering models, the MEMLS3&a model consisting of simulation of both active and  
6 passive microwave response (Wiesmann and Mätzler, 1999; Proksch et al., 2015) was applied.  
7 The expected backscatter and emission response against increasing SWE was simulated using  
8 a one-layer configuration. Observations from the second campaign season (2010-2011) were  
9 used as a reference.

10 With the exception of SWE, all model parameters were kept constant in simulations. Soil,  
11 snow and air temperatures were set at  $-5^{\circ}\text{C}$ . Snow density was kept at  $170\text{ kg m}^{-3}$ , which was  
12 the average value measured during NoSREx II. In brightness temperature simulations,  
13 downwelling sky brightness temperature (atmosphere + cosmic background) was estimated as  
14 18 and 38 K for 18.7 and 37 GHz, respectively. Soil reflectivity was estimated based on early  
15 season observations, resulting in vertically polarized reflectivity values from 0.015 to 0.03 and  
16 horizontally polarized reflectivity values from 0.03 to 0.09, from 10.2 to 37 GHz, respectively.  
17 For the active model, the specular part of the reflection was set at 0.75, and the cross-  
18 polarization ratio was assumed as 0.1. The mean slope of surface undulations was set at 0.05.  
19 The exponential correlation length required by MEMLS was not routinely measured during the  
20 campaign, except for short campaign periods. Therefore, in these simulations, the correlation  
21 length best fitting passive microwave simulations at vertical polarization was found iteratively,  
22 using 18.7 and 37 GHz measurements at vertical polarization as a reference: the vertically  
23 polarized emission was thought to be the least affected by the layered structure of snow cover.  
24 The iteration resulted in a value of  $p_{\text{ex}} = 0.25\text{ mm}$ . The same value was then used in simulations  
25 of emission at horizontal polarization, as well as simulation of backscattering. The correlation  
26 length was measured using the SMP in February 2011, with the average value being 0.21 mm;  
27 on the other hand, the average measured  $E$  during NoSREx II was 1.5 mm (see Figure 2b),  
28 which following an empirical relation provided by Durand et al. (2008), would equally  
29 correspond to  $p_{\text{ex}} = 0.21\text{ mm}$ . In order to visualize the effect of correlation length on simulations,  
30  $p_{\text{ex}}$  was varied by  $\pm 30\%$  to provide upper and lower bounds for model predictions. The  
31 improved Born approximation was applied to simulate the scattering coefficient in MEMLS  
32 (Mätzler and Wiesmann, 1999).

1 The result of the model run against *SnowScat* and *SodRad* observations is presented in Figure  
2 3. As vertically polarized passive microwave observations were used to provide the model fit,  
3 these can be seen to be mostly within the simulation bounds of  $p_{ex} \pm 30\%$ . For horizontal  
4 polarization, the simulation provides an overestimation especially for higher values of SWE.  
5 Using the same parameters, the active MEMLS3&a model reproduces well the *SnowScat* 10.2  
6 GHz observations. On the other hand, the level of Ku band response is underestimated by  
7 several dB. It is notable that using the baseline semi-empirical radiative transfer (sRT) model  
8 developed for CoReH2O, the X-band response was typically overestimated while Ku band  
9 response provided a good fit (ESA, 2012).

10

## 11 6 Discussion

12 Snow grain size, which presents the main source of information on snow microstructure for  
13 NoSREx, is particularly difficult to establish in the field. Research also indicates that the grain  
14 size by itself is insufficient to explain the full scattering behaviour of microwaves in snow (e.g.  
15 Mätzler, 2002). The problem aggravates with snow particles of increasing size and complex  
16 shape, as well as by sintering and clustering of snow grains. However, using data collected  
17 during NoSREx, Leppänen et al. (2015) demonstrated that visually established grain sizes  $E$   
18 correlated with optical grain sizes measured using an objective measure of SSA. Furthermore,  
19 Lemmetyinen et al. (2015) showed that an average grain size used to fit emission model  
20 predictions captured both the magnitude and the seasonal trend of the visually estimated grain  
21 sizes during NoSREx-II. Therefore, the information collected on  $E$  can be used at least as an  
22 indicator of snow microstructural evolution during the NoSREx campaigns, even if not  
23 employed directly in e.g. forward model simulations of emission and backscattering.

24 The NoSREx data has already proven useful for establishing novel relations between snow  
25 properties and microwave signatures. Chang et al. (2015) applied the *SnowScat* observations  
26 for comparisons of backscattering estimates using two derivations of the Dense Media  
27 Radiative Transfer (DMRT), the bicontinuous model and quasi-crystalline approximations  
28 (QCA). The bicontinuous approach is based on exact solutions of the Maxwell equations, while  
29 QCA is an analytical approximation. Both approaches showed reasonable agreement with  
30 *SnowScat* observations collected during the second campaign season. Furthermore, Tan et al.  
31 (2015) recently demonstrated the necessity of multiple scattering enhancement in DMRT, using

1 both active and passive observations from NoSREx for model evaluation. On the other hand,  
2 Leinss et al. (2015) applied *SnowScat* observations for differential interferometry, showing that  
3 the increase in SWE could be accurately obtained by exploiting the phase information retained  
4 in *SnowScat* observations. The high temporal resolution of *SnowScat* (three to four hours)  
5 allowed to mitigate decorrelation effects, while phase wrapping at the relatively high  
6 frequencies was addressed with a novel two-frequency approach. Data collected in the frame  
7 of NoSREx has also been exploited in recent studies focused on passive microwave signatures  
8 (e.g. Rautiainen et al., 2014; Pan et al., 2015).

9

## 10 **7 Conclusions**

11 The NoSREx campaign provides a near continuous time series of active and passive  
12 microwave signatures of seasonal snow cover in a natural environment over four winter  
13 seasons. The dataset is unique in providing signatures over several winter seasons from the  
14 same site, with each season exhibiting singular characteristics in both microwave  
15 backscattering and emission, as well as snow and soil properties. The dataset is freely available  
16 to science users (see Data availability).

17 Analysis of NoSREx datasets has already revealed several features of interest relating snow  
18 properties to the backscatter and emission, and the dataset has seen wide use in the field of  
19 developing advanced forward models for remote sensing observables in the microwave range.  
20 In particular, the collected data corroborate previous findings that correct determination of the  
21 snow microstructure is imperative for understanding microwave signatures. Future campaigns  
22 should increasingly make use of advanced methodologies for quantifying snow structural  
23 properties, including the snow microstructure. This will enable to develop new metrics relating  
24 snow properties to microwave signatures obtained from Earth Observing satellites.

25

## 26 **Acknowledgements**

27 The work was conducted under the European Space Agency project “Technical assistance for  
28 the deployment of an X- to Ku-band scatterometer during the NoSREx experiment” (ESA  
29 ESTEC contract 22671/09/NL/JA/ef). The staff at FMI-ARC are acknowledged for *in situ* data  
30 collection and operation of microwave instruments.

## 16 **Data availability**

17 The NoSREx consolidated datasets are available after registration on the ESA Earth  
18 Observations Campaign Data portal (<https://earth.esa.int/web/guest/campaigns>). *SnowScat* raw  
19 data are available for scientific use via FMI and Gamma remote sensing AG. Data from  
20 NoSREx IOPs are available for scientific o request via WSL-SLF. The time series of SSA  
21 profiles are available on separate request from FMI.

1

2 Table 1. *SnowScat* technical specifications.

Parameter	Value
Manufacturer	GAMMA Remote Sensing
Power:	230V, max ~ 60W
Weight:	~ 40 kg
Temperature Range:	-40° C to 40° C
Antenna:	dual pol, < 10° (3dB)
Antenna cross-pol iso:	< -20 dB
Frequency:	Stepped CW from 9.15 to 17.9 GHz
Incidence angle:	-40° to 110°
Azimuth angle:	-180° to 180°
Polarisation:	HH, HV, VV, VH
Dynamic range:	Receiver dynamic range > 80 dB with the 16 bit ADC
Signal bias:	< 0.5 dB

3

1

2 Table 2. *SodRad* technical specifications.

Parameter	Value
Manufacturer	Radiometer Physics GmbH
Power:	~300 W average, 500 W peak
Weight:	405 kg (including positioner)
Temperature Range:	-40° C to 45° C
Receiver & Antenna thermal stabilization	< 0.05 K
Antenna $\theta_{3dB}$	< 6.1°
Antenna sidelobe level:	< -30 dBc
Incidence angle:	30° < $\theta$ < 330°
Azimuth angle:	360°
Polarisation:	V and H
Frequencies:	10.65, 18.7, 36.5, 90 GHz
Bandwidth	400 MHz
System noise temperatures	< 900 K
Dynamic range:	0 – 350 K
System stability	1.0 K
Radiometric resolution	0.2 K RMS @ 1 s integration time
