**Abstract.** This paper focuses on major issues related to data reliability and MOBNET network performance in the AlpArray  
10 seismic experiments, in which twenty temporary broad-band stations of the Czech MOBNET pool of mobile stations have  
been involved. Currently used high-resolution scientific methods require high-quality data recorded for a sufficiently long  
time interval at observatories and during full time of operation of temporary stations. In this paper we present both new  
hardware and software tools that help to assure the high-quality standard of broad-band seismic data. Special attention is  
15 paid to issues like a detection of sensor mis-orientation, timing problems, exchange of record components and/or their  
polarity reversal, sensor mass centring, or anomalous channel amplitudes due to, e.g., imperfect gain. Thorough data-quality  
control should represent an integral constituent of seismic data recording, pre-processing and archiving, especially for data  
from temporary stations in passive seismic experiments. Large international seismic experiments require enormous efforts of  
scientists from different countries and institutions to gather hundreds of stations to be deployed in the field during a limited  
time period. In this paper, we demonstrate beneficial effects of the procedures we have developed for having a sufficiently  
20 large set of high-quality and reliable data from each group participating in field experiments.

## 1 Introduction

Data from passive seismic experiments of different lateral extent, with densely distributed stations, became crucial source of  
information for the modern research of the Earth interior. The USArray ([www.usarray.org](http://www.usarray.org)) or IberArray  
([iberarray.ictja.csic.es](http://iberarray.ictja.csic.es); Díaz et al., 2010) represent the large-scale temporary networks, whereas, e.g., TRANSALP  
25 (Lippitsch et al., 2003) or BOHEMA (Plomerová et al., 2007) belong to small-size passive experiments in central Europe.  
Participants of the AlpArray project, the European collaborative geoscience initiative (AlpArray Seismic Network, 2015;  
[www.alparray.ethz.ch](http://www.alparray.ethz.ch)), deployed the largest network of temporary broad-band station ever realized in Europe. The project  
focuses on the structure and evolution of the lithosphere-asthenosphere system beneath the greater Alpine area – the Alps  
and their forelands. The northern foreland of the Alps is formed by the Bohemian Massif, the easternmost outcrop of the

Variscan belt of the European plate. The project uses seismological as well as associated Earth science data for better understanding the geodynamics of the greater Alpine area and its seismic hazard. The area, studied by generations of geoscientists, comprises the orogenic system, where two large plates (Europe and Africa) have converged and interacted over time with several micro-plates of oceanic and continental provenances (Kissling et al., 2006; Handy et al., 2010 for reviews). Besides the Alpine structure itself, the Alps-Appennines, Alps-Dinarides and Alps-Bohemian Massif contacts in depth are of the particular interest within the AlpArray study. In addition to structural studies related to the orogenic system dominating Europe with the use of associated Earth sciences data (such as gravity, electro-magnetics, geology, etc.), several other topics as seismotectonics and earthquake hazard belong to the core of the project.

To achieve objectives of the project, it is necessary to apply various geological/geophysical imaging methods on data recorded by a homogeneous network of broad-band (BB) seismic stations in the greater Alpine area (Fig. 1). Though the area is in some parts densely covered by permanent seismic observatories, their distribution is far from being homogeneous. Therefore, the distribution of ~360 existing permanent stations have been complemented by ~260 temporary BB stations to create a relatively dense network of unprecedented large scale in Europe, with homogeneous station spacing of about 50 km.

The station spacing and station location is designed in such a way that for any site in the Alpine region there is always a station of the AlpArray Seismic Network (AASN) at a distance up to ~26 km. The temporary seismic network of such large extent requires intensive collaboration between many institutions (currently more than 45 institutions from 17 countries), combination of individual national/institutional seismic pools of temporary stations and coordination of their deployment, keeping the high-level maintenance and experienced handling. Thanks to the large extent of the array and density of the stations, results from seismic tomography and several other techniques applied on data collected during the unique passive experiment will shed light on the detailed 3D architecture of the crust and upper mantle. The project aims at imaging structures and understanding processes from the Earth's surface down to ~600 km in the mantle of this extremely complicated orogenic region.

The AlpArray area, set as a region delimited by a 250 km distance from the 800 m altitude isoline surrounding the Alps, covers a large portion of the Czech (CZ) part of the Bohemian Massif (BM). Ten BB observatories of the Czech Regional Seismological Network (CRSN), one permanent BB station of the West Bohemian Network (WEBNET) along with 20 temporary BB stations of the pool of seismic stations from MOBNET of the Institute of Geophysics, Czech Academy of Sciences (IG CAS), cover the area with the spacing required (Fig. 1). The Czech team of the AASN (coded Z3 in the European Integrated Data Archive (EIDA) system) is responsible for the deployment and maintenance of the MOBNET stations in the Czech part of the AlpArray, as well as for completeness and correctness of recorded seismic data, transferred to the EIDA centres. Data from the Czech temporary stations of the Z3 networks code ([www.fdsn.org/networks/detail/Z3\\_2015/](http://www.fdsn.org/networks/detail/Z3_2015/)), with the access restricted according to the AlpArray rules, are transferred to

ODC ([www.orfeus-eu.org/data/eida/nodes/](http://www.orfeus-eu.org/data/eida/nodes/)), while data from the Czech permanent stations with open access continue being stored in the GEOFON ([geofon.gfz-potsdam.de](http://geofon.gfz-potsdam.de)).

Main purpose of this paper is to describe technical parameters of the MOBNET stations, to present newly developed control units for setting sensor and data acquisition systems (DAS) and to document significance of careful data-quality control, which could help other groups of the AlpArray project in preparing their seismic data for archiving. Special attention is paid to detection of sensor mis-orientation, timing problems, exchanged of components and/or their polarity reversal, mass centring problems, or anomalous channel amplitudes due to, e.g., an imperfect gain. Elimination of all these concerns is of the extreme importance for keeping the high quality of archived seismological data, which is crucial for success of the AlpArray project, as well as of any passive seismic experiment.

## 2 Deployment of MOBNET stations within the AlpArray project

Twenty stations of the MOBNET pool have been deployed in the Bohemian Massif (BM) since August 2015, as a part of the AASN (Fig. 2). Before, the stations had been deployed for approximately one-year period during 2014-2015 in the Eastern Alpine Seismic Investigation (EASI) project, the first implemented AlpArray Complementary Experiment (Table 1, see Fig. 1). The EASI transect was composed of 55 broadband seismic stations, configured in a zig-zag pattern on either side of the central longitude line of 13.35° E, with the north-south distance between stations of 10 km. The transect spanned a region of ~540 km long, between the Erzgebirge Mts. at the Czech-German border in the North and the Adriatic Sea, near Trieste in the South. The distance of each station to either side of the central line was ~6 km. We followed the general recommendations of the Technical strategy of the AlpArray ([www.alparray.ethz.ch](http://www.alparray.ethz.ch)) and kept the stations within 1.5 km of the target location, if topographic, field and infrastructure conditions allowed.

The northernmost stations AAE01-AAE20 (Fig. 2) of the MOBNET pool involved in the AlpArray–EASI were equipped mostly with the STS-2 seismometers, two CMG-3T and three CMG-3ESP seismometers, and the GAIA DAS. The stations were installed preferably in vaults of castles/chateaux, churches, or suitable abandoned buildings. Figure 3 shows an example of a station location, seismometer installation, quality of the site and, noise level, etc. (see also S1-S19, supplements). Keeping notation of Molinari et al. (2016), we can characterize the location as of urban free-field site, only exceptionally as of building site (Table 1). The stations ran at the autonomous regime and reported daily their state-of-health in SMS messages. Altogether, we recorded 280 GB of data stored in mseed which contribute to the AlpArray-EASI studies including tomography, ambient noise analysis and receiver functions, considering anisotropy in all three types of investigations, as well as in shear-wave splitting analyses. The depth range of scientific investigations encompasses the crust and the mantle lithosphere, down to the lithosphere-asthenosphere boundary (LAB).

The EASI field measurement was finished in August 2015 and twenty MOBNET stations were re-installed at new sites, selected according to the AASN geometry (see Fig. 2). With the exception of A090A, all other stations operate offline. Data from the offline stations are recorded on flash cards with capacity exceeding at least 4 times space needed for data sampled at rate of 100 sps and collected in three-month intervals to be checked and supplied to the ODC-EIDA node. Similarly to the  
5 EASI transect, most of the AASN-CZ sites are of urban free-field types (Table 1, Fig. 4, S20-S38). Though the region of the BM is densely populated with local industrial and agricultural sources of high-frequency noise, the stations meet requested noise limits (Peterson, 1993) as it is shown for the example in Figure 4 (see also S20-S38). Only at about 30 % of stations, noise exceeds the limit on vertical components at long-period range ( $T > 100$  s) (e.g., S33). Some of the stations exhibit distinct seasonal variations of noise level, which results in exceeding the noise limit in the long-period range on horizontal  
10 components (Fig. 5), (Wolin et al., 2015).

Figure 6 shows current status of data availability from the MOBNET stations included in the AlpArray passive field experiment. Data recorded by GAIA stations are stored at sampling rate of 100 sps on flash cards with capacity of recordings exceeding 3-4 times the three-month interval of data collection. In case of the AlpArray-EASI complementary project in  
15 2014-2015, we retrieved 96 % of the data at each station, on average (Fig. 6a). As concerns the ongoing AlpArray project, the data completeness is 99 % (for period by October 2016) for the MOBNET stations. Several gaps in data were caused by summer thunderstorms that damaged electrical supplies (Fig. 6b). Though almost all our stations operate offline, the data completeness for MOBNET stations in the AASN is similar to that for stations of the Austrian or Swiss parts of the AASN with an online data transmission (Fuchs et al., 2016; Molinari et al., 2016).

### 20 **3 Seismometer and GAIA control and calibration devices**

Our broad-band temporary stations involved in the AlpArray project are equipped mostly with broad-band seismometers STS-2 and several CMG (Table 1), and with data acquisition systems GAIA developed by the VISTEC company ([www.vistec.cz](http://www.vistec.cz)). To assure high-degree reliability of the seismometer-DAS pairs performance, we have developed four special control devices for seismometers of different types and one for the GAIA DAS. In general, these boxes generate  
25 pulses into the systems and compare amplitudes of input and output signals. The devices enable to calibrate sensors and data acquisition systems, as well as to check in-situ gain of all individual components and polarity of the recorded signal. The hardware check facilitates identification/verification of any malfunction of the systems and enables their immediate treatment, often directly in the field.

#### **3.1 Guralp host box (CMG-3T and CMG-3ESP(C))**

30 Guralp host box (Fig. 7a) becomes an integral constituent of each seismometer CMG-3T and CMG-3ESP(C) and it is an analogy of the hand-held unit of the Guralp company provenience, or the host box of the STS-2 seismometer. Our Guralp

host box is incorporated between the seismometer and the GAIA DAS, and enables fundamental handlings of the seismometer, namely pendulums arrestment (lock/unlock) and their centring. Busy LED light informs about state of the seismometer. The host box is equipped with a connector for the Guralp control and calibration unit (see Sect. 3.2), or for a remote seismometer control (e.g., via GSM).

### 5 **3.2 Guralp control and calibration unit (CMG-3T and CMG-3ESP(C))**

This device (Fig. 7b) enables to calibrate a seismometer by the unit step signal or Dirac delta pulse. It has also an input for external calibrating signal of an arbitrary shape. Polarity of the calibrating signal can be changed and the signal size can be altered in two levels. There is a switch between the calibration mode and the display mode of pendulum positions of the Z, NS and EW components. A push button centres the pendulums.

### 10 **3.3 Guralp centring unit (CMG-40T)**

Guralp centring unit (Fig. 7c) was developed for seismometer pendulums without electronic centring, e.g., CMG-40T. For the pendulum position checking, it is necessary to disconnect the seismometer from the DAS and to connect the Guralp centring unit. Deviation of the pendulum from the central position is proportional to the mass position voltage. Pendulum centring requires the mass position voltage close to zero. The unit has a built-in accumulator, which supplies energy to  
15 seismometer during the control. In case of insufficient accumulator capacity, the accumulator can be plug-in via an external charger. The Guralp centring unit, developed for seismometers with only manual pendulum centring, can be used also for pendulum position check of seismometers with electronic control, but then the centring unit does not enable pendulum centring.

### **3.4 STS-2 control and calibration unit**

20 STS-2 control and calibration unit (Fig. 7d) has been developed for centring pendulums and for seismometer calibration. The device is being connected to the “Monitor” connector of the host box provided by the seismometer producer. The host box forms the integral part of the system, through which the STS-2 seismometers is supplied with electric energy. The STS-2 control and calibration unit displays positions of the pendulums for the U, V and W components, or offsets of the standard Z, NS, EW components of the output signal. The unit is equipped with a button of automatic centring of pendulum position  
25 (auto-zero push button), connected in parallel to similar button of the host box. The 120 s / 1 s switch of the control and calibration unit changes modes between the broad-band and short-period regime.

Each of the U, V and W components can be calibrated separately with the unit step signal or the Dirac delta pulse. There is also a switch for an external calibrating signal of an arbitrary shape, e.g., of a sinusoidal signal. If the components are calibrated together, calibration currents and their polarities are chosen so that the output signals (components Z, NS, EW)  
30 have the same amplitudes and polarities. This procedure guarantees correct functioning of the seismometer.

### 3.5 GAIA gain and calibration unit

GAIA gain and calibration unit (Fig. 7e) checks and calibrates inputs into the GAIA DAS, but it can be used for calibration of any type of digitizers as well (Kinometrics, Nanometrics, Reftek, Guralp etc.), after being equipped with corresponding connector reductions. The unit enables to calibrate analogue inputs, to set order of channels, to evaluate cross-talks between the channels, to measure channel amplification and sensitivity (the gain, i.e., the counts to voltage conversion). Number of channels undergoing calibration and channel polarity can be changed. Differential mode and the plus or minus single-ended regimes can be switched over. The calibration is done by voltage jump of a known size. Built-in generator of saw-shape calibrating voltage serves for a judgement of linearity of the input signal.

## 4 Data quality control and assurance

10 Currently used high-resolution seismological methods require high-quality data inputs. The high level of data quality has to be stable during a long-time interval for seismological observatories and for a full time of operation of temporary stations within passive experiments. Data quality control represents the necessary step for achievement of the high-quality seismic data. We differentiate (1) in-situ controls with technical equipment, applied during installation of stations and their servicing, and (2) ex-post software controls, applied on downloaded data.

### 15 4.1 Seismic noise

Identification of ambient noise conditions is nowadays a standard procedure when searching sites suitable for station installation. However, the level of ambient noise has to be watched continuously, to monitor potential changes in conditions of recordings, or to detect technical problems of a station. According to the AlpArray working group requirements average noise level should be 20 dB lower than the New High Noise Model (NHNM; Peterson, 1993) on all components within the 20 1-10 Hz frequency range. The same noise level is requested only for the vertical component in the long-period range (30-200 s). Because ambient noise is usually higher on horizontal components, an average noise level is recommended to be only 10 dB less than the NHNM. To follow the ambient noise level, we use the seismic probabilistic power spectral density (PPSD) procedure by McNamara and Buland (2004) and Custodio et al. (2014) which is a part of ObsPy module (Krischer et al., 2015).

25 Figure 8 shows the PPSD medians for all MOBNET stations included in both configurations within the AlpArray project. While the level of noise for periods below 10 s fulfils the noise requirements, noise on horizontal components for periods higher than 10 s is often larger, especially in winter time, but still acceptable for temporary deployments. One has to bear in mind that a compromise between optimal site conditions and the required station spacing has to be accomplished. An enhanced thermal insulation of seismometers might decrease the ambient noise level at longer periods. On the other hand, 30

the difference between the noise levels on horizontal and vertical components can be exploited as one of tools to decipher potential exchange of components, as we describe below.

#### 4.2 Sensor orientation

Exact orientation of seismometers in the geographic co-ordinate system is one of the most important tasks during station  
5 installations. Mis-oriented sensors affect results of procedures based on modern three component seismological observations  
and can lead to false interpretations (Ekström and Busby, 2008; Vecsey et al., 2014; Wang et al., 2016). Determination of the  
northward direction has been routinely done for years with the use of standard compass, with the best accuracy of  $\pm 5^\circ$  in case  
of no magnetic disturbances in nearby surroundings. However, such accuracy is no more sufficient. The top-level current  
practice is to orient seismometers with the use of the high-precision gyrocompass measurement during a station installation  
10 and to repeat the measurements during station services. Repeated measurements are desirable to avoid any seismometer mis-  
orientation resulting from, e.g., an accidental shift of sensors by a person or an animal, as well as due to a nearby strong  
lightning, which all we have experienced. To determine correct sensor orientations, one can use Rayleigh-wave polarization-  
angle method (e.g. Stachnik et al., 2012), in which differences between the Rayleigh-wave polarizations and their theoretical  
back-azimuths are plotted in dependence on origin times of seismic events. For determining an exact moment of the change  
15 of sensor orientation, the Rayleigh-wave polarization-angle method can be combined with daily amplitude-mean plots. After  
determining a day, when the sensor happens to be mis-oriented, one has to search changes in the data signal.

When installing our stations for the AlpArray-EASI transect, we oriented the seismometers carefully, but only according to a  
standard compass. Later we checked the orientation of all sensors with a fiberoptic gyrocompass. We have found deviations  
20 larger than  $5^\circ$  from the true North at 9 of 20 stations (Table 2) and extremely large deviations in orientation at two of them  
(AAE13  $N=282^\circ$  and AAE04  $N=341^\circ$ ). Two other stations (AAE13 and AAE18) changed significantly their orientation  
during the experiment: by  $8^\circ$  and  $7^\circ$ , respectively. We have used the polarization-angle method for a rough estimate of a  
moment, when orientation of the sensors has been changed, and daily means and signal plots for setting exact time of the  
sensor re-orientations.

25 Sensors of all our stations involved in the currently running AASN (A071-A090) have been installed with the use of our  
gyrocompass and their orientation is regularly checked. During about a one-year period of the array operation, we have  
already recorded three unwanted changes of sensor orientation due to a human intervention. Besides the necessary sensor re-  
orientation on spot, previous inaccuracies in sensor orientations have been corrected in the metadata.

#### 30 4.3 Timing issues

Correct timing is crucial for kinematic studies based on exact arrival times of seismic waves. Incorrect time decreases  
accuracy of picking individual phases, causes false phase identification or a loss of data at all. Timing errors of 1 s or smaller

are not clearly evident during routine seismological analyses, but can be revealed from station “log” files, if provided by the registration system, from carefully kept service sheets, or from headers of mseed data. Existing time gaps and overlaps can be calculated from the time of the first sample, number of samples and sampling rate in each mseed block.

- 5 Here we address three important timing problems: (1) the leap second recorded with a delay, (2) switch between the UTC and GPS times and (3) malfunction of an oscillator tuning the station time. The leap second is introduced into the Coordinated Universal Time (UTC) usually once or twice per year in order to keep the UTC day time close to the mean solar time. The leap second is usually applied at midnight, while clocks in data acquisition systems are being synchronized later, e.g., with a 30-90 minute delay. Moreover, the leap-second correction is applied at individual stations differently, because
- 10 times of their synchronizations differ. It is thus necessary to shift the leap second right to the midnight for all temporary stations before data archiving.

Sometimes, a problem can arise due to a wrong synchronization of the inner time (UTC) of a station and the GPS time. This can happen when the coordinated universal time in the “almanac” transmitted by satellites disappears from the memory of a

15 station for some reasons (e.g., low voltage of inner battery, incorrect satellite signal recorded, etc.). Currently, the UTC and GPS times differ by 18 seconds. Thus the UTC/GPS time switch results in the 18 s shift of the time in recorded data. Such time shift can last for several hours or a full day and requires to be corrected as well.

Failure of an oscillator tuning the station time could cause a jump or a linear increase of timing error in data. However, such

20 difficulties should occur exceptionally. If it happens and we are able to identify such a problem and reconstruct a real timing, it is necessary to correct times directly in the mseed data, which is more difficult than applying corrections in the metadata. When checking our data, we have found an oscillator failure at station A087A, which resulted in a final time error of 0.18 s during 8 days in October 2015.

#### 4.4 Interchange of components and polarity reversal

- 25 Results from different studies dealing with waveforms, i.e., with amplitudes of seismic waves, sometimes raise a suspicion that the three components of seismograms need not be correctly labelled, i.e., the components could be interchanged. The simplest way to verify the correct indication of the three components is a comparison of waveforms for a selected strong teleseismic event recorded on several nearby stations, which we call the waveform similarity method (Fig. 9a). Several other methods can be used as well, e.g., a visualization of daily means of signal amplitudes, sometimes called offsets (Fig. 9b), or
- 30 a comparison of noise levels on the vertical and horizontal components in PPSD. In case of correct component identification, the noise level on the vertical component should be lower than that on the horizontal components. Correction of exchanged components can be done either in the metadata, or preferably directly in the mseed data.

Reversed polarity of components, arising from different technical reasons, is not as rare as one would expect. Polarity reversal can be easily identified by the waveform similarity method for nearby stations. We can also use a single-station method that is based on a search of Rayleigh wave polarization (the polarization-angle method). Then the differences between the Rayleigh wave polarization and the theoretical back-azimuth are plotted in dependence on theoretical back-azimuths. If only one horizontal component is reversed, the differences change linearly between  $-180^\circ$  and  $+180^\circ$ . The zero difference reflects the fact that the reversed component does not play any role in the component summation and identifies the components with the correct polarity (see Fig. 10a; the EW component is the correct one). In case of the reversed polarity on the Z component, or if both horizontal components are reversed, the differences between the Rayleigh-wave polarizations and the theoretical back-azimuths attain values around  $180^\circ$  for all back-azimuths (Fig. 10b). Moreover, we have identified also an interchange of both horizontal components in combination with their polarity reversals. This complicated case can be solved by combination of the methods mentioned above and by a careful analysis of the results. Similarly to the component interchange, the component reversal can be corrected either in the metadata, or preferably in the mseed data.

#### 4.5 Gain imperfection

Anomalous signal amplitudes due to imperfectly set gains on one or more components are not very frequent in comparison with the sensor mis-orientations, but their danger for data analysis procedures is similarly large. We can recognize anomalously large or low recorded amplitudes in two ways: first, by means of technical devices, such as control and calibration units (see Sect. 3), and second, by means of software methods applied on recorded seismic signals.

The software inspection of the amplitude size is based on evaluation of noise, which is the only continuous signal in seismic data. We have implemented a new method which compares ratios of normalized power spectra between the three components in a range of 4-8 seconds. In this range, the secondary microseisms are substantially larger than noise from local sources. Directionality of the microseisms due to different sources is eliminated by normalizing the spectrum of each trace via an average spectrum calculated over the traces of surrounding stations. The spectra are calculated within certain time intervals, e.g., weeks, months, or a whole time range. Resulting ratios of the spectra provide a running record of individual channel sensitivity and allow us to follow potential changes of the amplitudes in a course of time. In combination with sporadic in-situ gain controls by the Gain and calibration box (Sect. 3.5), we have reliable control of potential anomalous size of recorded amplitudes and thus we can determine when a detected change in the gain occurred.

We document a successful use of the hardware and software methods on data from the two seismic experiments. During the data processing, we have found that the power spectra of the EW components at stations AAE14 (EASI) and A087A (AASN) are lower by approximately 11 dB (Fig. 11a). The NS/Z component ratio is close to zero, while ratios EW/Z and EW/NS, where the EW component is involved, are 10 dB lower. Station documentations identified that stations AAE14 and A087A were equipped with identical sensor and data acquisition system. Therefore, afterwards we tested the gain of each

component of the sensor-DAS pair with the calibration boxes as described in Sect. 3. The test confirmed the amplitudes recorded on the EW component were 3.6 times smaller ( $20 \cdot \log 3.6 = 11$  dB) than it should be. The error in the acquisition system was identified and repaired. If such error is identified by an in-situ measurement, then it can be immediately eliminated (DAS can be repaired or changed, as it was possible in case of running station A087A). Metadata of A087A for a previous period, as well as the metadata of the AAE14 station active in the finished EASI measurements were corrected subsequently. In another case we have found that either the amplitudes on EW components are about two-times larger, or the gains of the NS and Z components are lower by  $\sim 6$  dB at stations AAE15 (EASI) and A088A (AlpArray) (Fig. 11b). Results of the normalized PPSD ratios are only relative ones. The absolute value - the half-size gain compared with the declared one, was identified by an in-situ measurement with the use of the STS-2 control and calibration unit (see Sect. 3.4). Source of the low gain was localized in a defect cable of the seismometer. The double-checked gain levels of each component (by the hardware unit and by the software calculating the normalized PPSD ratios) enabled us to correct reliably the gains in the station metadata files and thus to correct anomalous amplitudes.

#### 4.6 Drift of sensor mass position

One of artefacts seen in the PPSD reflects a failure of the automatic mass re-centring of the sensor (McNamara and Buland, 2004). If a seismometer is not able to correct a drift of the mass position itself, amplitudes of seismic signals become saturated. Signal corresponding to such a time period has a characteristic “flat” spectrum shape (Fig. 12a). The flat course in an interval of  $\sim 0.3$ -50 s differs clearly from the shape of the noise distribution modulated by secondary microseisms. The large undesirable drift of the mass position from its central position limits the dynamic range of the sensor and therefore, it needs to be identified as soon as possible. Running information about a sensor mass “drift” comes from the size of a sum of counts in one-hour interval on each component provided by GAIA DAS in daily SMS reports. Besides this hardware checks, daily means of recorded amplitudes (Fig. 12b) serve as an independent fast and easy tool for ex-post identification of the mass centring problem. Moreover, complementing the daily amplitude means by their standard deviations and absolute values of daily amplitude extremes (maxima or minima) we can better assess the state of health of each station (Fig. 12c).

#### 5 Conclusions

We have developed both the hardware and software tools to contribute with reliable high-quality waveform data to passive seismic experiments. At present, twenty broad-band stations of the Czech MOBNET pool of temporary stations are incorporated in the AlpArray Seismic Network. The stations were also deployed in the preceding AlpArray EASI complementary experiment. To assure high-degree reliability of the STS-2/CMG seismometer-DAS pairs performance, we have developed four special control devices for seismometers of different types and one for the GAIA DAS. The devices calibrate both the sensors and data acquisition systems in-situ and check gain and polarity of all components. We emphasise the importance of precise sensor orientation by a gyrocompass both during station installations and of its regular checks

during the field measurements. Information extracted from power spectra density, spectra ratios, daily amplitude means and other parameters, followed by the designed procedures in routine data processing, allow us to identify several problems, e.g., imperfectly set gains, interchange of components and polarity reversals, insufficient sensor mass centring and last, but not the least, time issues. The hardware control in-situ and the ex-post software data checking represent the double check of data quality. The former removes problems immediately in the field, the latter allows restoring data back in time, until the moment when a problem occurred. We believe that the newly developed control and calibration units for setting sensor-DAS systems and the documentation of the significance of careful data-quality control, could be helpful for other groups participating in collaborative passive seismic experiments.

### Data availability

10 Data from the MOBNET pool as a part of the AlpArray project is stored in EIDA ([www.orefus-eu.org/eida/](http://www.orefus-eu.org/eida/)), currently with restricted access (<http://www.alparray.ethz.ch/research/complementary-experiments/easi/data-access-citation/> and [http://www.alparray.ethz.ch/seismic\\_network/backbone/data-access/](http://www.alparray.ethz.ch/seismic_network/backbone/data-access/)).

### Team list

The complete member list of the AlpArray Working Group can be found at <http://www.alparray.ethz.ch>.

### 15 Acknowledgements

Cooperation with participants of the AlpArray projects is greatly appreciated. The research of the Czech team was supported by grants No. M100121201 of the Czech Academy of Sciences and partly by No. P210-12-2381 of the Grant Agency of the Czech Republic. Data acquisition from permanent observatories was supported by the project of Large research infrastructure CzechGeo/EPOS, grants Nos. LM2010008 and LM2015079. Several figures and calculations have been prepared with the use of the Generic Mapping Tools (Wessel and Smith, 1998) and ObsPy (Krischer et al., 2015).

**AAE08**  
**Manětín**

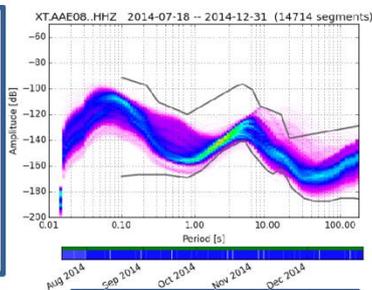

**INSTALLATION**

**EQUIPMENT**

Start : 17.7.2014    Sensor : STS 2 120 s  
 Stop : 23.9.2015    Depth : 0m  
 Lat : 49.9910    Recorder : Gaia 1  
 Lon : 13.2322    Power : electricity grid  
 Alt : 409 m    Data : miniSeed, 6 GB

The station is located in the former stables of Manětín chateau.  
 Seismometer is built on a concrete floor.  
 The GPS antenna is brought out through the window, length - 5 m, direction - S, view partially obscured.  
 Geomorphology: Rakovník Uplands.  
 Subsoil: phyllite.

**Figure 3: Example of installation of one of the broad-band MOBNET stations in the AlpArray-EASI experiment - AAE08 Manětín.**

**A076A**  
**Maková Hora**

**INSTALLATION**

**EQUIPMENT**

Start : 8.9.2015  
 Lat : 49.6168  
 Lon : 14.1494  
 Alt : 532 m

Sensor : CMG-3T 120 s  
 Depth : 3 m  
 Recorder : Gaia 1  
 Power : electricity grid

The station is located on the lower ground floor of the former rectory pilgrimage church at Maková Hora (Poppy Mountain). Upper ground floor is occasionally used for recreational purposes. Seismometer is installed in the shaft on concrete pillars built on bedrock. The GPS antenna is brought out through the window, length - 5 m, direction - S, view open. Geomorphology: Benešov Uplands. Subsoil: orthogneiss.

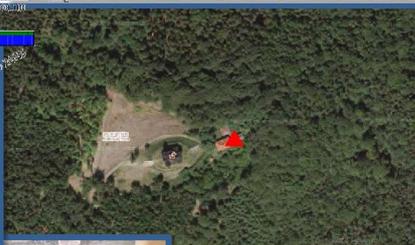

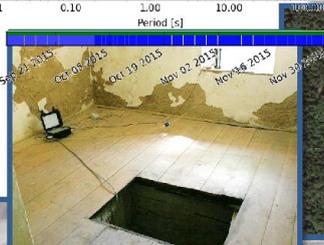

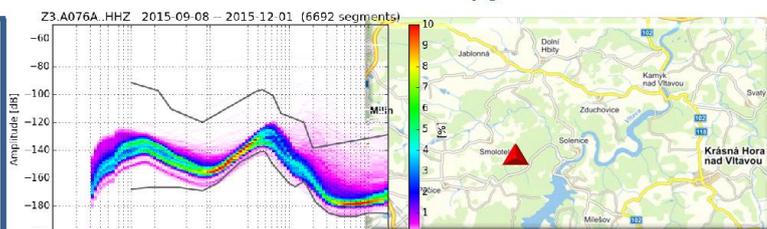

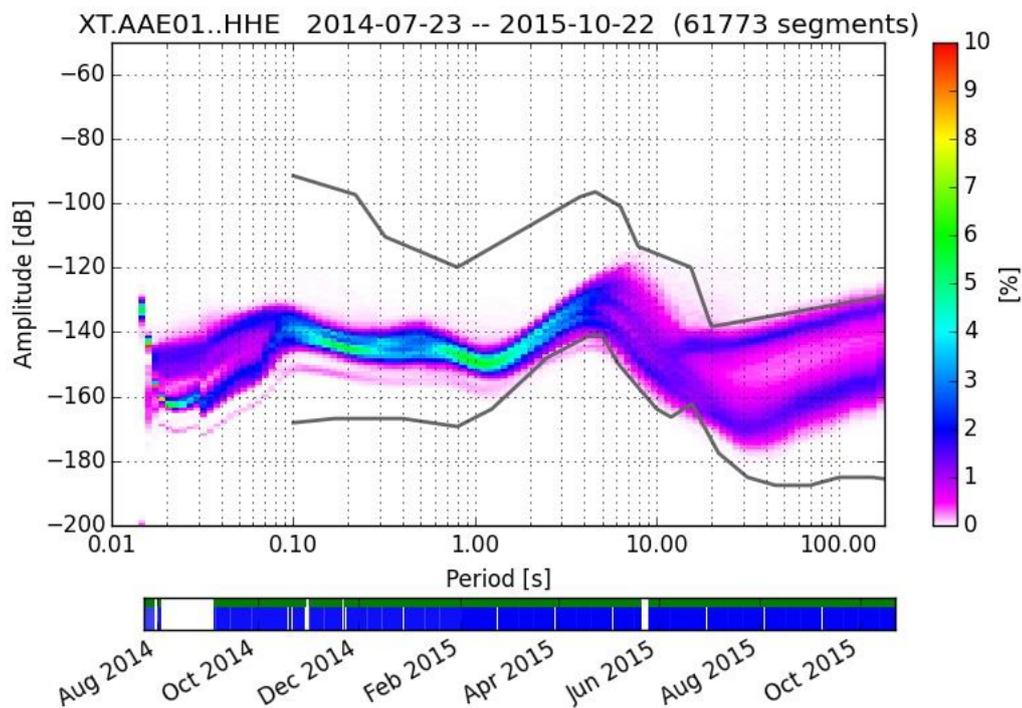

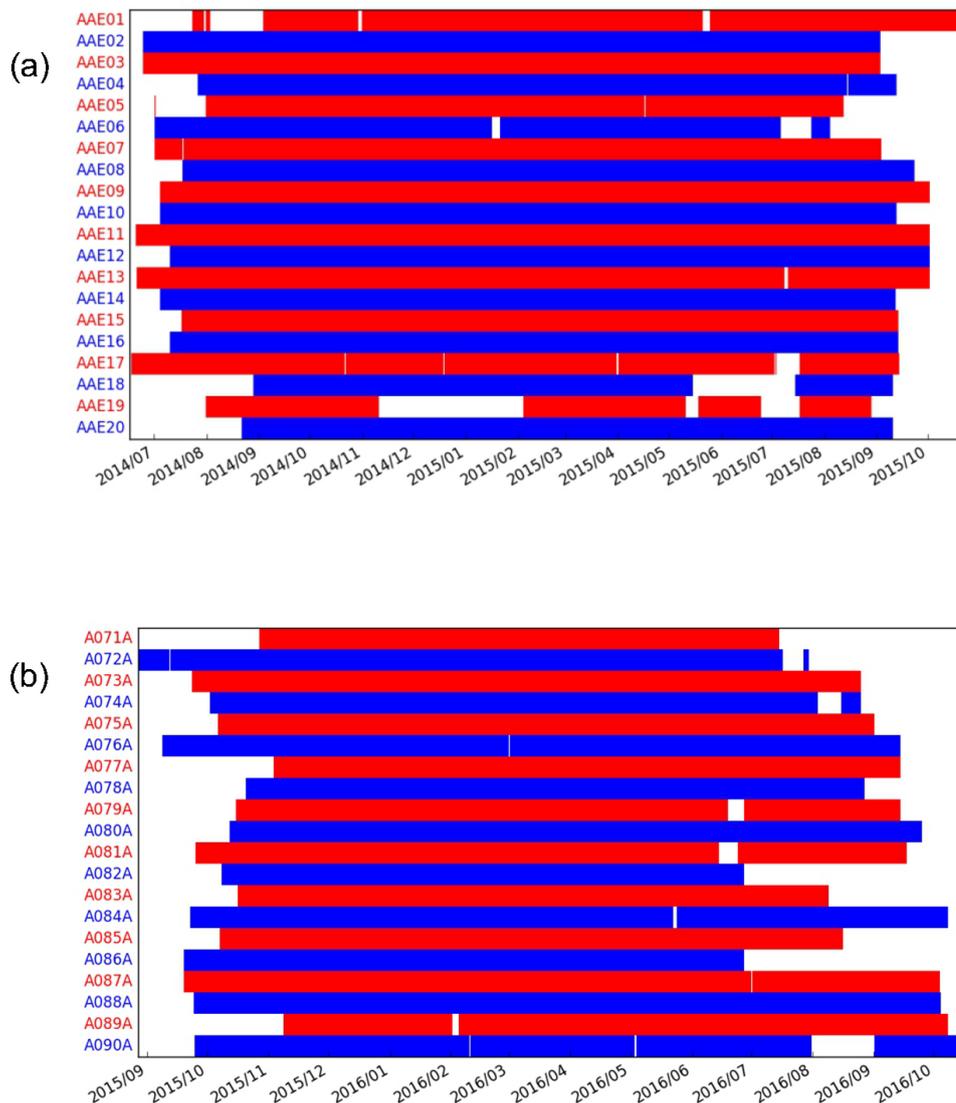

Figure 4: Example of installation of one of the broad-band MOBNET stations in the AlpArray Seismic Network (AASN) - A076A Maková Hora.

**Figure 5: Probabilistic power spectra density on the horizontal component of the AAE01 station of the AlpArray-EASI experiment. The example shows a noise level during the winter time relative to low-noise level during the summer period, in which the noise is far below the limit of the noise model (grey curves; Peterson, 1993).**

**Figure 6: Data completeness of MOBNET stations in the AlpArray projects: (a) in the EASI complementary field measurements and (b) in the ongoing AlpArray experiment.**

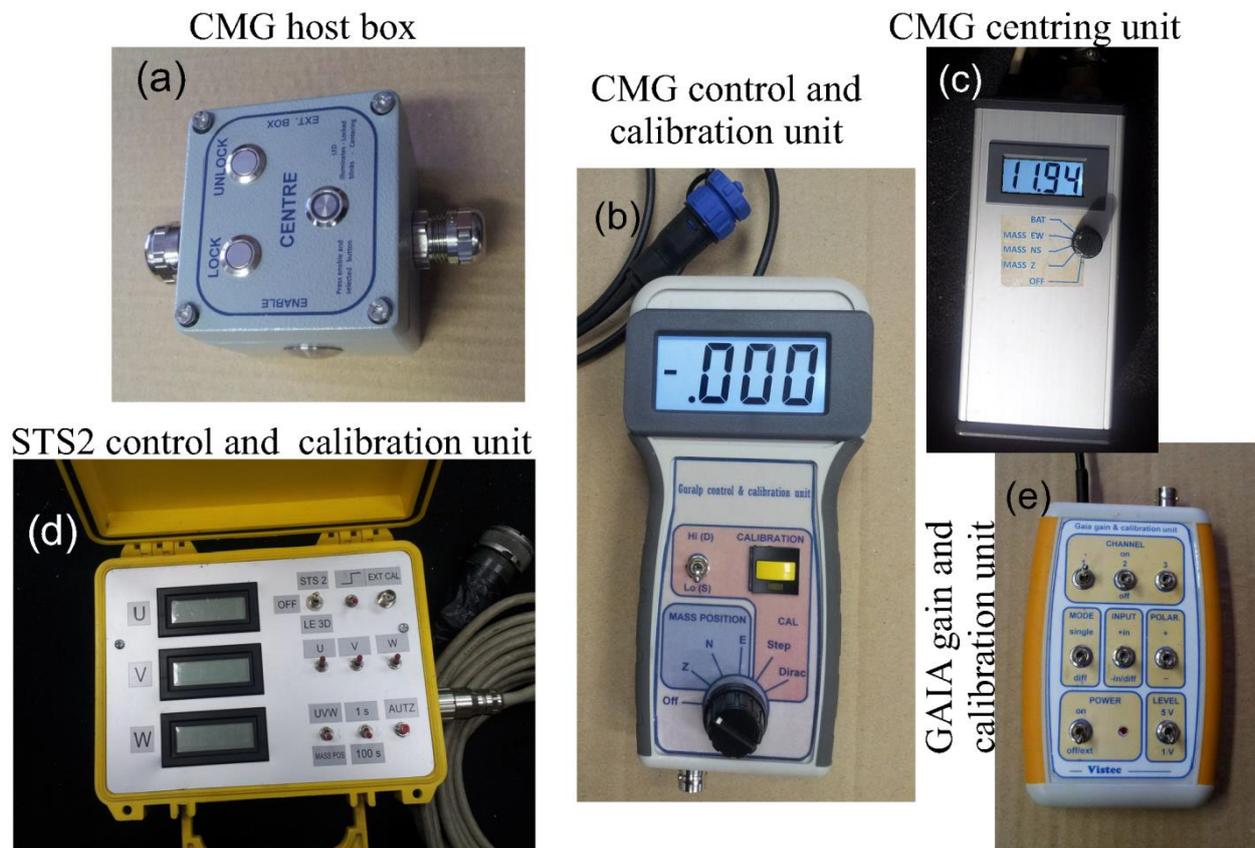

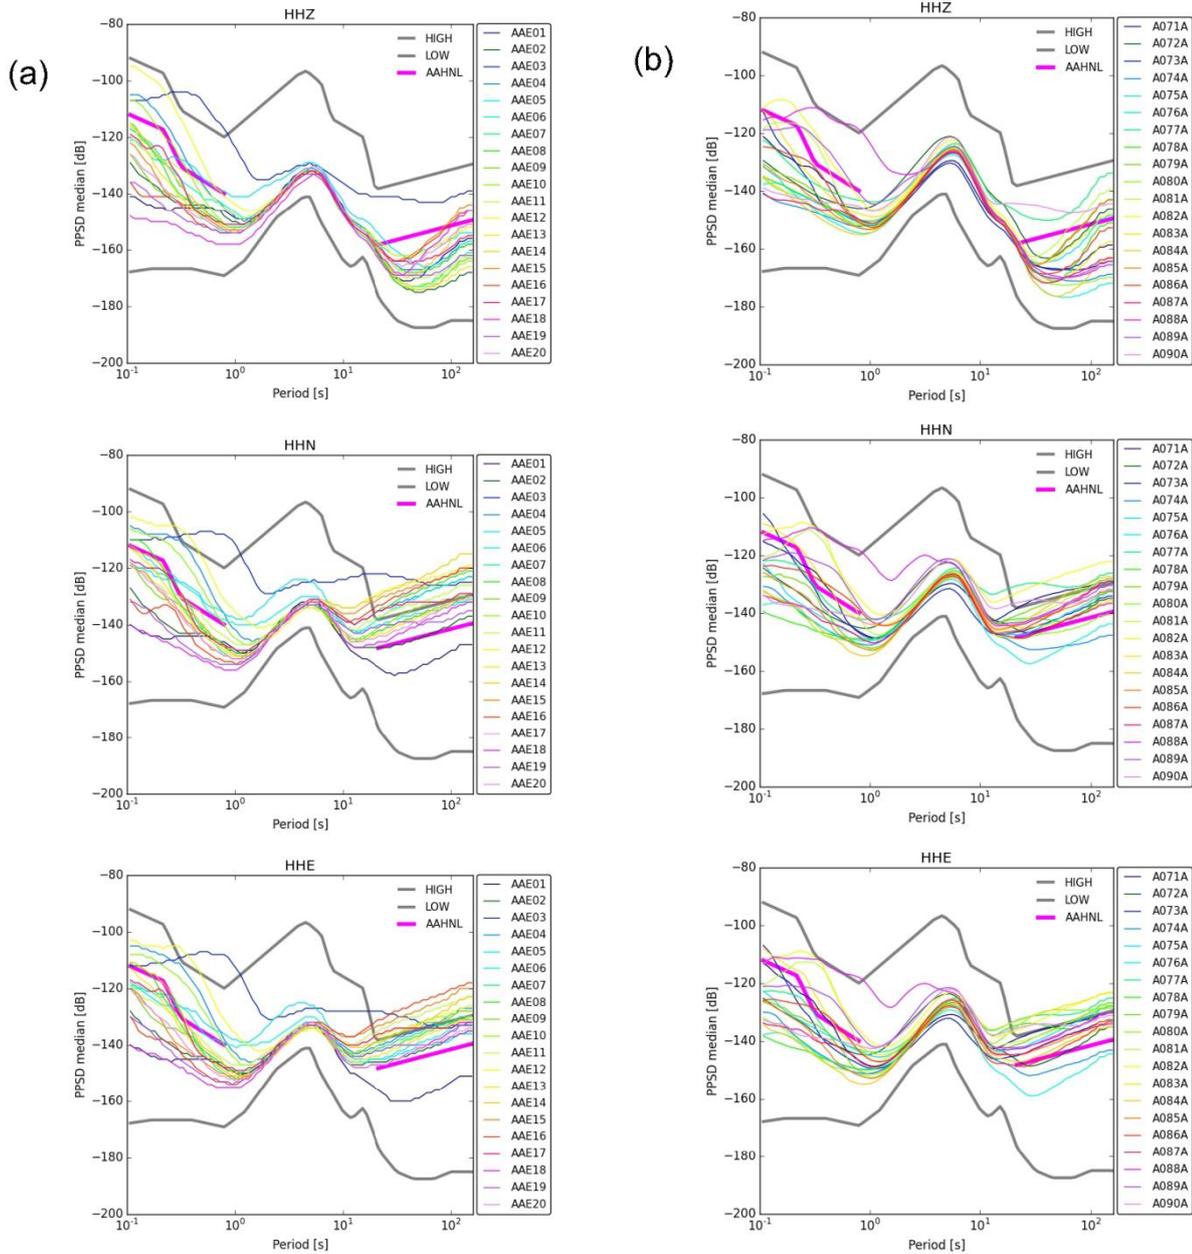

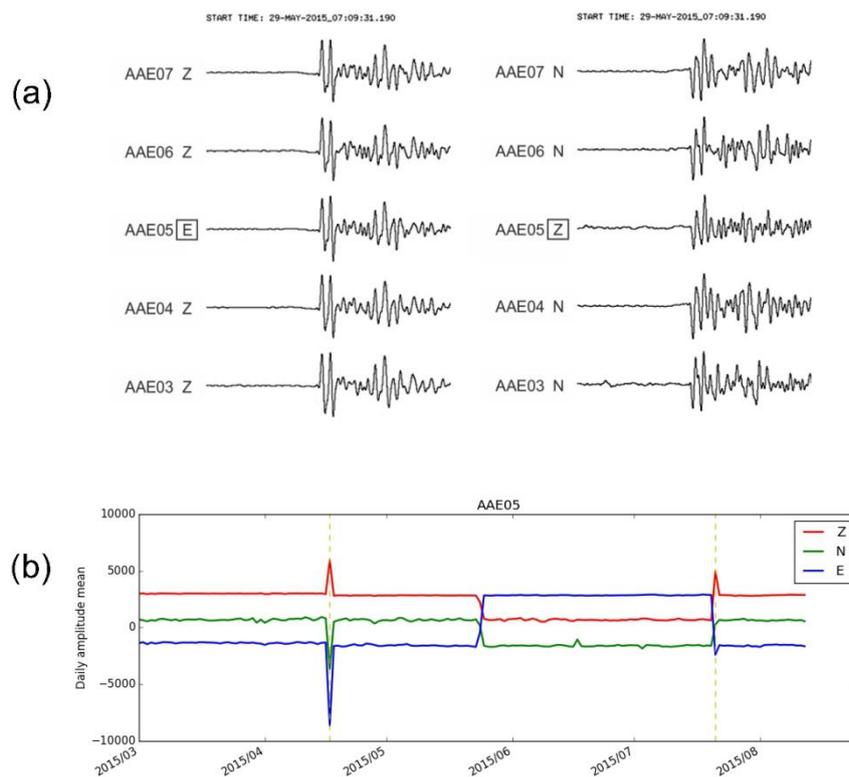

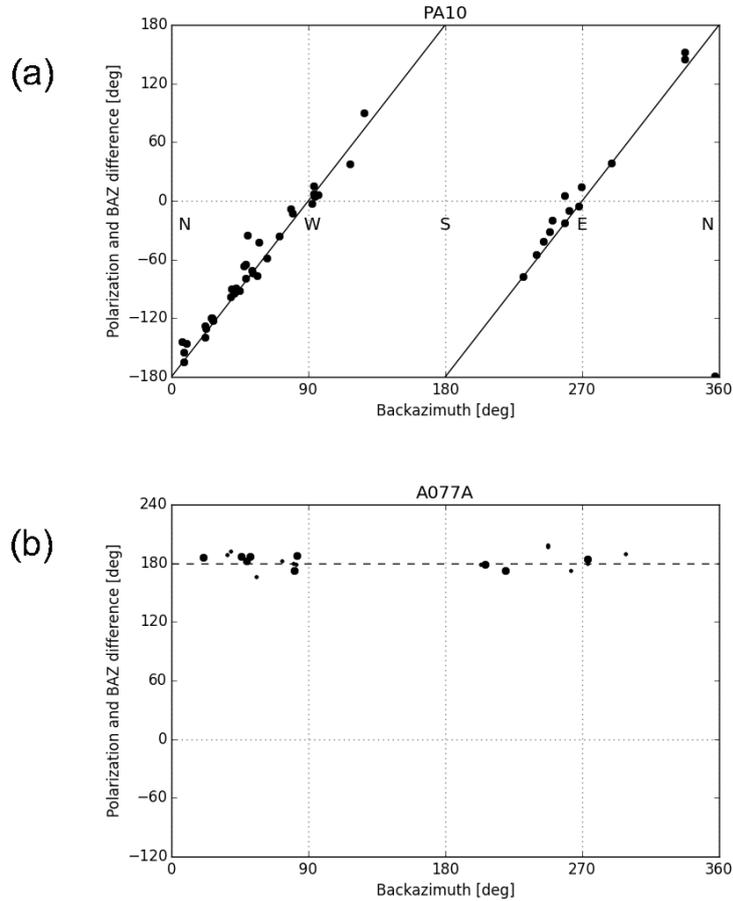

Figure 7: Control and calibration units developed for the broad-band seismometers and GAIA DAS to guarantee the high-quality of recorded data.

**Figure 8: Medians of probabilistic power spectral density (PPSD) of seismic noise at the MOBNET stations involved (a) in the AlpArray-EASI complementary experiment and (b) in the AlpArray Seismic Network (AASN). The thick red line marks the upper limit of recommended noise level between the low- and high-noise level models (Peterson, 1993).**

**Figure 9: The waveform similarity method showing the interchange of the EW and Z components (a) at the AAE05 station. Daily amplitude means (b) of all three components at the AAE05 station during June – July, 2015 indicated the interchange of all three components. Vertical dashed lines show dates of station servicing.**

5 **Figure 10: Differences between the Rayleigh wave polarizations and event theoretical back-azimuths (BAZ) in dependence on the theoretical back-azimuth. Linear dependence of the difference (a) identifies the polarity reversal of the NS component. Polarization of waves arriving from the East or West is not affected by the reversed NS component. Station PA10 of the PASSEQ experiment 2006-2008 (Vecsey et al., 2014) is used as an example. (b) Constant difference of  $\sim 180^\circ$  corresponds to the polarity reversal of both horizontal components at the A077A station of AASN.**

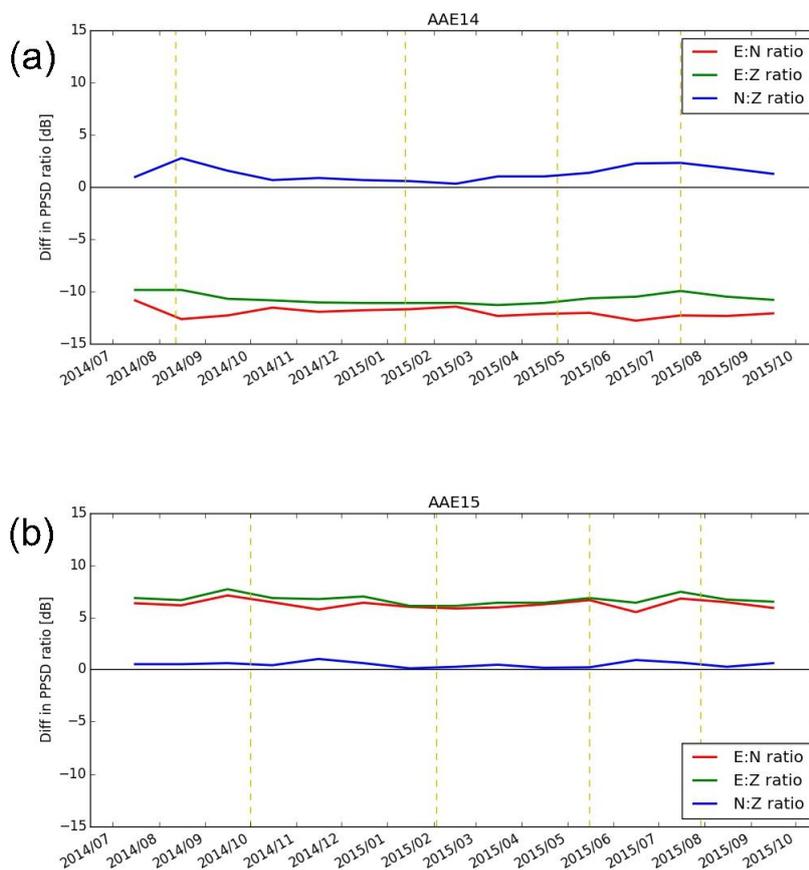

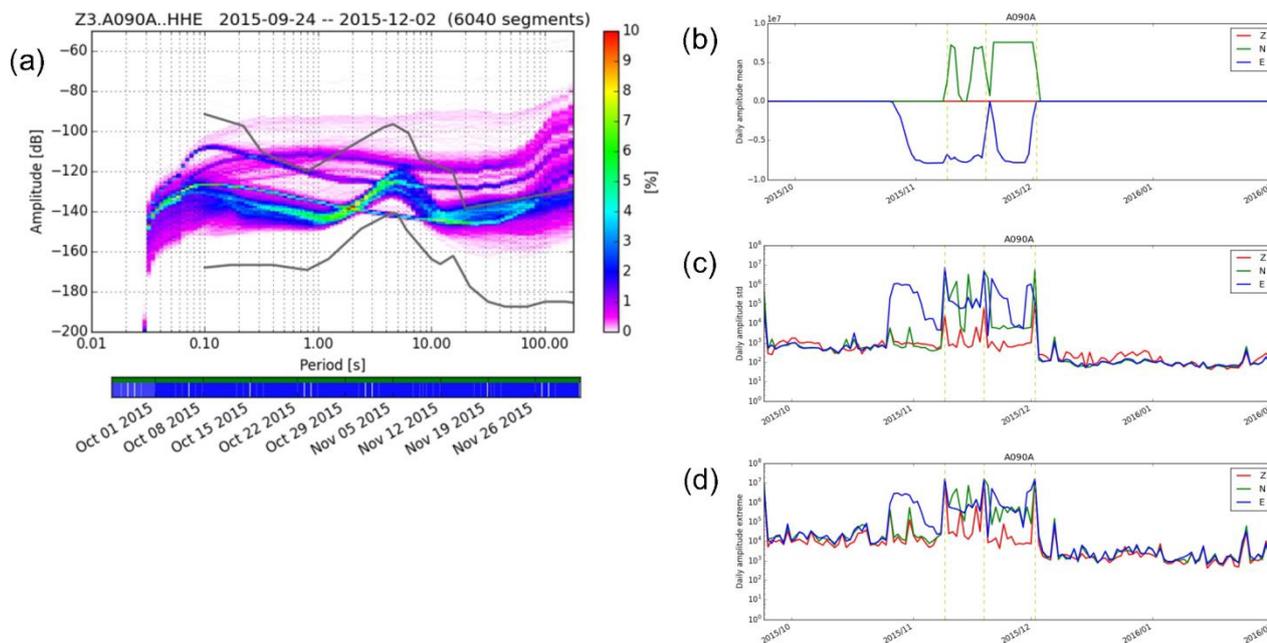

Figure 11: Seismometer gain check. Monthly averages of normalized power spectra ratios identify imperfect gains of the EW component (a) and of both the NS and EW components (b).

**Figure 12: Sensor mass centring. Flat curves in PPSD (a), daily means of amplitudes (b), their standard deviations (c) and absolute values of daily amplitude extreme (d) identify the failure of the automatic mass re-centring.**
